Dear Editor

The new Coronavirus (COVID-19) pandemic continues to affect human health worldwide seriously. The disease is spread mainly via large droplets. A lot of cases are asymptomatic, while the others are symptomatic. Mainly symptoms are fever, cough, shortness of breath, while anosmia, conjunctivitis and gastroenteritis are less common. Until an effective vaccine or treatment is not found the most important means of prevention remains to be social isolation. COVID-19 patients showed lymphopenia, abnormal respiratory findings, and increased levels of plasma pro-inflammatory cytokines [1]. SARS-CoV-2 virus is a respiratory system attacking agent causing severe pneumonia and other vital systemic
features including cardiac injury [2]. Furthermore, hematologic and coagulation abnormalities, such as elevated ferritin, D-Dimer, prolongation of prothrombin time/activated partial thromboplastin time, and thrombocytopenia are common among these patients [3].

There remain a considerable number of questions that need to be answered to be able to understand this virus. Although, while the complement system is an critical component of the innate immune system, uncontrolled activation of complements can cause severe disease, like, thrombotic microangiopathy.

Of note, hypocomplementemia was described various viral infection like parvovirus B19, Ebola virus and hepatitis C infections [4-6]. Recently, it was showed that the complement activation, contribute to severe acute respiratory syndrome coronavirus (SARS-CoV) pathogenesis in mices [7]. Also, a case-control study showed that lower serum mannose-binding lectin (MBL) in 353 patients with SARS-CoV, 19–23 days after the onset of disease were determined. They found that the median serum level of MBL in these patients (0.733 [IQR, 0.263–1.796] mg/mL) was significantly lower than that in 1167 control individuals (1.369 [IQR, 0.572–2.598] mg/mL). These findings suggested that MBL-deficient patients were more susceptible to SARS-CoV, and they provide insight into the possible mechanisms of the innate immune response to SARS-CoV infection [8]. To our knowledge, there is no published data yet nor in vitro neither in vivo demonstrate the relationship between COVID-19 and C3 and C4 levels. In our center, we retrospectively analysed the association of hypocomplementemia and COVID-19 infection.
We retrospectively analysed C3 and C4 levels of fifty seven COVID-19 positive patients, including 29 intubated intensive care unit (ICU) patients and 28 non-ICU ward patients. Serum complement levels were measured at admission. The median value of C3 and C4 levels in ICU patients was (1.15 [IQR 0.91-1.39] g/L) and (0.24 [IQR 0.12-0.34] g/L), whereas in non-ICU patients there were (1.48 IQR [1.24-1.72] g/L) and (0.30 g/L [IQR 0.24-0.40]), respectively (P>0.05). In terms of tendency to decreased C3 levels, the difference between two groups was insignificant.

According to our findings, there was no significant difference in terms of C3 and C4 levels in both ICU and non-ICU COVID-19 patients. For this reason, we think that, C3 and C4 levels cannot be used to show disease activation. Therefore, we need more clinical studies to confirm our outcomes.
